A brief overview of quantum computing

Complex Systems Summer School, Santa Fe

Tom Carter

http://cogs.csustan.edu/~tom/quantum

June 29, 1999
Our general topics:

- Hilbert spaces and quantum mechanics.
- Tensor products and entangled quantum states.
- Quantum bits (qubits), the physics of computation, elements of quantum computing.
- Tractability of computation (e.g., factoring and boolean satisfiability).
- Models for quantum computing.
- Suggestions for practical implementations of quantum computers.
- Problems and prospects.
“There was a time when the newspapers said that only 12 men understood the theory of relativity. I do not believe there ever was such a time. There might have been a time when only 1 man did, because he was the only guy who caught on, before he wrote his paper. But after people read the paper a lot of people understood the theory of relativity in some way or other, certainly more than 12. On the other hand, I think I can safely say that nobody understands quantum mechanics”

-Richard Feynman
Hilbert space setting for quantum mechanics

- A Hilbert space $H$ is a complete normed vector space over $\mathbb{C}$:

1. $H$ is a vector space over $\mathbb{C}$

2. There is an inner product $\langle \cdot | \cdot \rangle : H \times H \to \mathbb{C}$ which is conjugate linear:
   \[
   \langle v | w \rangle = \overline{\langle w | v \rangle} \\
   \langle v | \alpha w \rangle = \alpha \langle v | w \rangle \text{ for } \alpha \in \mathbb{C} \\
   \langle v + w | z \rangle = \langle v | z \rangle + \langle w | z \rangle \\
   \langle v | v \rangle \geq 0 \text{ and } \langle v | v \rangle = 0 \text{ iff } v = 0
   \]

3. From the inner product, as usual, we define the norm of a vector:
   \[
   ||v||^2 = \langle v | v \rangle
   \]

4. $H$ is complete with respect to the norm.
• We will typically use the bra/ket notation: $|v\rangle$ is a vector in $H$, and $\langle v|$ is the covector which is the conjugate transpose of $v$.

• A unitary operator $U : H \to H$ is a linear mapping whose conjugate transpose is its inverse: $U^\dagger = U^{-1}$

• Unitary operators are norm preserving: $\|Uv\|^2 = \langle v|U^\dagger U|v\rangle = \langle v|v\rangle = \|v\|^2$

• We will think of a quantum state as a (normalized) vector $|v\rangle \in H$. For math folks, we are in effect working in Complex projective space, normalizing to 1 so that the probabilities make sense.
• The dynamical evolution of a quantum system is expressed as a unitary operator acting on the quantum state.

• Eigenvalues of a unitary matrix are of the form $e^{i\omega}$ where $\omega$ is a real-valued angle. A unitary operator is in effect a rotation.

• A measurement consists of applying an operator $O$ to a quantum state $v$. To correspond to a classical observable, $O$ must be Hermitian, $O^\dagger = O$, so that all its eigenvalues are real. If one of its eigenvalues $\lambda$ is associated with a single eigenvector $u_\lambda$, then we observe the value $\lambda$ with probability $|\langle v | u_\lambda \rangle|^2$ (i.e., the square of the length of the projection along $u_\lambda$).
• In general, if there is more than one eigenvector \( u_\lambda \) associated with the eigenvalue \( \lambda \), we let \( P_\lambda \) be the projection operator onto the subspace spanned by the eigenvectors, and the probability of observing \( \lambda \) when the system is in state \( v \) is \( \|P_\lambda v\|^2 \).

• Most projection operators do not commute with each other, and are not invertible. Therefore, we can expect that the order in which we do measurements will matter, and that doing a measurement will irreversibly change the state of the quantum system.
• Just for reference, a typical expression of Schrödinger’s equation looks like

\[
-\frac{\hbar^2}{2m_e} \nabla^2 + V(x, y, z) \Ψ = i\hbar \frac{\partial}{\partial t} \Ψ
\]

with general solution

\[
Ψ(x, y, z, t) = \sum_{n=0}^{\infty} c_n Ψ_n(x, y, z) \exp \left( -\frac{iE_n t}{\hbar} \right)
\]

• Another way to think of this is that we have to find the Hamiltonian \( H \) which generates evolution according to:

\[
H |Ψ(t)\rangle = i\hbar \frac{\partial}{\partial t} |Ψ(t)\rangle.
\]

In our context, we will have to solve for \( H \) given a desired \( U \):

\[
|Ψ_f\rangle = \exp \left(-\frac{i}{\hbar} \int H dt \right) |Ψ_0\rangle = U |Ψ_0\rangle
\]

A solution for \( H \) always exists, as long as the linear operator \( U \) is unitary.
Tensor products

• We can form tensor products of a wide variety of objects. For example:

1. The tensor product of an $n$ dimensional vector $u$ and an $m$ dimensional vector $v$ is an $nm$ dimensional vector $u \otimes v$.

2. If $A$ and $B$ are operators on $n$ and $m$ dimensional vectors, respectively, then $A \otimes B$ is an operator on $nm$ dimensional vectors.

3. If $H_1$ and $H_2$ are Hilbert spaces, then $H_1 \otimes H_2$ is also a Hilbert space. If $H_1$ and $H_2$ are finite dimensional with bases $\{u_1, u_2, \ldots, u_n\}$ and $\{v_1, v_2, \ldots, v_m\}$ respectively, then $H_1 \otimes H_2$ has dimension $nm$ with basis $\{u_i \otimes v_j | 1 \leq i \leq n, 1 \leq j \leq m\}$. 
• The conjugate transpose distributes over tensor products:

\[(A \otimes B)^\dagger = A^\dagger \otimes B^\dagger.\]

• The tensor product of several matrices is unitary if and only if each one of the matrices is unitary up to a constant. Let \(U = A_1 \otimes \ldots \otimes A_n\). Then \(U\) is unitary if \(A_i^\dagger A_i = k_i I\) and \(\prod_i k_i = 1\).

\[U^\dagger U = (A_1^\dagger \otimes \ldots \otimes A_n^\dagger)(A_1 \otimes \ldots \otimes A_n)\]
\[= A_1^\dagger A_1 \otimes \ldots \otimes A_n^\dagger A_n\]
\[= k_1 I \otimes \ldots \otimes k_n I\]
\[= I\]
Qubits

- A quantum bit, or qubit, is a unit vector in a two dimensional complex vector space for which a particular orthonormal basis, denoted by \{|0\rangle, |1\rangle\}, has been fixed. It is important to notice that the basis vector |0\rangle is NOT the zero vector of the vector space.

- For example, the basis |0\rangle and |1\rangle may correspond to the |↑\rangle and |→\rangle polarizations of a photon respectively, or to the polarizations |↗\rangle and |↖\rangle. Or |0\rangle and |1\rangle could correspond to the spin-up and spin-down states (|↑\rangle and |↓\rangle) of an electron.
• For the purposes of quantum computing, the basis states $|0\rangle$ and $|1\rangle$ are taken to encode the classical bit values 0 and 1 respectively.

• Unlike classical bits however, qubits can be in a superposition of $|0\rangle$ and $|1\rangle$ such as $a|0\rangle + b|1\rangle$ where $a$ and $b$ are complex numbers such that $|a|^2 + |b|^2 = 1$.

• If such a superposition is measured with respect to the basis $\{ |0\rangle, |1\rangle \}$, the probability that the measured value is $|0\rangle$ is $|a|^2$ and the probability that the measured value is $|1\rangle$ is $|b|^2$. 
• Key properties of quantum bits:

1. A qubit can be in a superposition state of 0 and 1.

2. Measurement of a qubit in a superposition state will yield probabilistic results.

3. Measurement of a qubit changes the state to the one measured.

4. There is no transformation which exactly copies all qubits. This is known as the ‘no cloning’ principle. Interestingly, it is nonetheless possible to ‘teleport’ a quantum state, but in the process, the original quantum state is destroyed . . .
"The Universe is full of magical things patiently waiting for our wits to grow sharper."

- Eden Phillpotts

"Any sufficiently advanced technology is indistinguishable from magic."

- Arthur C. Clarke
Entangled quantum states

• If we have available more than one (physical) qubit, we may be able to entangle them. The tensor product of the Hilbert spaces for the individual qubits is the appropriate model for these entangled systems.

• For example, if we have two qubits with bases \{\ket{0}_1, \ket{1}_1\} and \{\ket{0}_2, \ket{1}_2\} respectively, the tensor product space has the basis

\{\ket{0}_1 \otimes \ket{0}_2, \ket{0}_1 \otimes \ket{1}_2, \ket{1}_1 \otimes \ket{0}_2, \ket{1}_1 \otimes \ket{1}_2\}.

We can (conveniently) denote this basis as

\{\ket{00}, \ket{01}, \ket{10}, \ket{11}\}.
• More generally, if we have $n$ qubits to which we can apply common measurements, we will be working in the $2^n$-dimensional Hilbert space with basis
\[
\{|00\ldots00\rangle, |00\ldots01\rangle, \ldots, |11\ldots10\rangle, |11\ldots11\rangle\}
\]

• A typical quantum state for an $n$-qubit system is
\[
\sum_{i=0}^{2^n-1} a_i |i\rangle
\]
where $a_i \in \mathbb{C}$, $\sum |a_i|^2 = 1$, and $\{|i\rangle\}$ is the basis, with (in our notation) $i$ written as an $n$-bit binary number.
Shocking

“Anyone who is not shocked by quantum theory has not understood it.” –Neils Bohr

“One is led to a new notion of unbroken wholeness which denies the classical analyzability of the world into separately and independently existing parts. The inseparable quantum interconnectedness of the whole universe is the fundamental reality.” –David Bohm

“I don’t like it, and I’m sorry I ever had anything to do with it.” –Erwin Schrodinger
Quantum Computing

• This exponential growth in number of states, together with the interference of states and the ability to subject the entire space to transformations (either unitary dynamical evolution of the system, or a measurement projection into an eigenvector subspace), provides the foundation for quantum computing.

• In general, if we had enough time, we could simulate any quantum computation with a classical computer. The real potential value of quantum computers lies in speeding up computations.
• The critical questions are:

1. How much can we speed up particular computations?

2. Can we build a physical implementation of a quantum computer?

3. Does the implementation allow us to carry out useful computations before decoherence interactions with the environment disturb the system too much?

4. Given the “no cloning” principle, can we develop quantum error detection/correction systems? In particular, we can’t just take measurements for error control since measurements have irreversible effects on quantum systems.
Simple quantum gates

- These are some examples of useful single-qubit quantum state transformations. Because of linearity, the transformations are fully specified by their effect on the basis vectors. The associated matrix is also shown.

\[ I : \begin{align*} |0\rangle \rightarrow |0\rangle & \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \\ |1\rangle \rightarrow |1\rangle & \end{align*} \]

\[ \sigma_x : \begin{align*} |0\rangle \rightarrow |1\rangle & \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \\ |1\rangle \rightarrow |0\rangle & \end{align*} \]

\[ \sigma_y : \begin{align*} |0\rangle \rightarrow |1\rangle & \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \\ |1\rangle \rightarrow -|0\rangle & \end{align*} \]

\[ \sigma_z : \begin{align*} |0\rangle \rightarrow |0\rangle & \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \\ |1\rangle \rightarrow -|1\rangle & \end{align*} \]

**\( I \)** is the identity transformation, **\( \sigma_x \)** is negation, **\( \sigma_z \)** is a phase shift operation, and **\( \sigma_y = \sigma_z \sigma_x \)** is a combination of both. All these gates are unitary. For example

\[ \sigma_y \sigma_y^\dagger = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = I. \]
Another important single-bit transformation is the Hadamard transformation defined by

\[
H : |0\rangle \rightarrow \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)
\]
\[
|1\rangle \rightarrow \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle).
\]

Applied to \( n \) bits each in the \( |0\rangle \) state, the transformation generates a superposition of all \( 2^n \) possible states.

\[
(H \otimes H \otimes \cdots \otimes H)|00\ldots0\rangle = \frac{1}{\sqrt{2^n}} \left(((|0\rangle + |1\rangle) \otimes \cdots \otimes (|0\rangle + |1\rangle)\right)
\]
\[
= \frac{1}{\sqrt{2^n}} \sum_{x=0}^{2^n-1} |x\rangle.
\]

The transformation acting on \( n \) bits is called the Walsh or Walsh-Hadamard transformation \( W \).
• An important example of a two qubit gate is the controlled-not gate, $C_{\text{not}}$, which complements the second bit if the first bit is 1 and leaves the bit unchanged otherwise.

$$C_{\text{not}}: \begin{align*}
|00\rangle & \rightarrow |00\rangle \\
|01\rangle & \rightarrow |01\rangle \\
|10\rangle & \rightarrow |11\rangle \\
|11\rangle & \rightarrow |10\rangle
\end{align*}$$

\[
\begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & 1 & 0
\end{bmatrix}
\]

The transformation $C_{\text{not}}$ is unitary since $C_{\text{not}}^\dagger = C_{\text{not}}$ and $C_{\text{not}}C_{\text{not}} = I$. The $C_{\text{not}}$ gate cannot be decomposed into a tensor product of two single-bit transformations.

• It is useful to have graphical representations of quantum state transformations, especially when several transformations are combined. The controlled-not gate $C_{\text{not}}$ is typically represented by a circuit of the form

\[\text{\begin{tikzpicture}[scale=0.5]
\draw (0,0) -- (1,0) node[midway, above] {$\times$};
\draw (0,-1) -- (1,-1) node[midway, below] {$\text{\textbullet}$};
\end{tikzpicture}}\]
The open circle indicates the control bit, and the $\times$ indicates the conditional negation of the subject bit. In general there can be multiple control bits. Some authors use a solid circle to indicate negative control, in which the subject bit is toggled when the control bit is 0.

Similarly, the controlled-controlled-not, which negates the last bit of three if and only if the first two are both 1, has the following graphical representation.

![Controlled-controlled-not diagram]

Single bit operations are graphically represented by appropriately labelled boxes as shown.

![Single bit operations diagram]
• The three-bit controlled-controlled-not gate or Toffoli gate is also an instance of this conditional definition:

\[ T = |0\rangle \langle 0| \otimes I \otimes I + |1\rangle \langle 1| \otimes C_{\text{not}}. \]

\[ T : \]
\[
|000\rangle \rightarrow |000\rangle \\
|001\rangle \rightarrow |001\rangle \\
|010\rangle \rightarrow |010\rangle \\
|011\rangle \rightarrow |011\rangle \\
|100\rangle \rightarrow |100\rangle \\
|101\rangle \rightarrow |101\rangle \\
|110\rangle \rightarrow |111\rangle \\
|111\rangle \rightarrow |110\rangle \\
\]

\( T \) can be used to construct a complete set of the classical boolean connectives and thus general combinatory circuits since it can be used to construct the not and and operators in the following way:

\[ T|1,1,x\rangle = |1,1,\sim x\rangle \]

\[ T|x,y,0\rangle = |x,y,x \land y\rangle \]
Tractability of computation

- We can generally categorize computational algorithms according to how the resources needed for execution of the algorithm increase as we increase the size of the input. Typical resources are time and (storage) space. In different contexts, we may be interested in worst-case or average-case performance of the algorithm. For theoretical purposes, we will typically be interested in large input sets . . .

- The hope of quantum computing is that problems that are difficult or impossible for classical computers to solve can be handled by quantum computers.
• A standard mechanism for comparing the growth of functions with domain \( \mathbb{N} \) is “big-Oh.” One way of defining this notion is to associate each function with a set of functions. We can then compare algorithms by looking at their “big-Oh” categories.

• Given a function \( f \), we define \( O(f) \) by:

\[
g \in O(f) \iff \exists c > 0 \text{ and } N \geq 0 \text{ such that } |g(n)| \leq c|f(n)| \text{ for all } n \geq N.
\]

• We further define \( \theta(f) \) by:

\[
g \in \theta(f) \text{ iff } g \in O(f) \text{ and } f \in O(g).
\]
In general we will consider the run-time of algorithms in terms of the growth of the number of elementary computer operations as a function of the number of bits in the (encoded) input. Some important categories – an algorithm’s run-time $f$ is:

1. Logarithmic if $f \in \theta(\log(n))$.

2. Linear if $f \in \theta(n)$.

3. Quadratic if $f \in \theta(n^2)$.

4. Polynomial if $f \in \theta(P(n))$ for some polynomial $P(n)$.

5. Exponential if $f \in \theta(b^n)$ for some constant $b > 1$.

6. Factorial if $f \in \theta(n!)$.
• Typically we say that a problem is \textit{tractable} if (we know) there exists an algorithm whose run-time is (at worst) polynomial that solves the problem. Otherwise, we call the problem \textit{intractable}.

• There are many problems which have the interesting property that if someone (an oracle?) provides you with a solution to the problem, you can tell in polynomial time whether what they provided you actually is a solution. Problems with this property are called Non-deterministically Polynomial, or NP, problems. One way to think about this property is to imagine that we have arbitrarily many machines available. We let each machine work on one possible solution, and whichever machine finds the (a) solution lets us know.
There are some even more interesting NP problems which are universal for the class of NP problems. These are called NP-complete problems. A problem $S$ is NP-complete if $S$ is NP and, there exists a polynomial time algorithm that allows us to translate any NP problem into an instance of $S$. If we could find a polynomial time algorithm to solve a single NP-complete problem, we would then have a polynomial time solution for all NP problems.
• Some examples:

1. Factoring a number is NP. First, we recognize that if $M$ is the number we want to factor, then the input size $m$ is approximately $\log(M)$ (that is, the input size is the number of digits in the number). The elementary school algorithm (try dividing by each number less than $\sqrt{M}$) has run-time approximately $10^m$, which is exponential in the number of digits. On the other hand, if someone hands you two numbers they claim are factors of $M$, you can check by multiplying, which takes on the order of $m^2$ operations.

It is worth noting that there is a polynomial time algorithm to determine whether or not a number is prime, but for composite numbers, this
algorithm does not provide a factorization. Factoring is a particularly important example because various encryption algorithms such as RSA (used in the PGP software) depend for their security on the difficulty of factoring numbers with several hundred digits.
2. Satisfiability of a boolean expression is NP-complete. Suppose we have \( n \) boolean variables \( \{b_1, b_2, \ldots, b_n\} \) (each with the possible values 0 and 1). We can form a general boolean expression from these variables and their negations:

\[
f(b_1, b_2, \ldots, b_n) = \bigwedge_{k} \bigvee_{i,j \leq n} (b_i, \sim b_j).
\]

A solution to such a problem is an assignment of values 0 or 1 to each of the \( b_i \) such that \( f(b_1, b_2, \ldots, b_n) = 1 \). There are \( 2^n \) possible assignments of values. We can check an individual possible solution in polynomial time, but there are exponentially many possibilities to check. If we could develop a feasible quantum computation for this problem, we would in some sense resolve the traditional \( P \neq NP \) problem . . .
3. The discrete Fourier transform of a sequence $\vec{a} = \langle a_j \rangle_{j=0}^{q-1}$ is the sequence $\vec{A} = \langle A_k \rangle_{k=0}^{q-1}$ where

$$A_k = \frac{1}{\sqrt{q}} \sum_{j=0}^{q-1} a_j e^{\frac{2\pi ijk}{q}}$$

One way to think about this is that $\vec{A} = F \vec{a}$ where the linear transformation $F$ is given by:

$$[F]_{j,k} = \frac{1}{\sqrt{q}} e^{\frac{2\pi ijk}{q}}$$

Note that the inverse of $F$ is $F^\dagger$ — that is,

$$[F^{-1}]_{k,j} = \frac{1}{\sqrt{q}} e^{-\frac{2\pi ijk}{q}}.$$

Suggestively, this says that the discrete Fourier transform is a unitary operation.

The action of this transformation on a vector of dimension $q$ looks as though
it would take the $q^2$ operations of matrix multiplication, but there is enough structure that the classical fast Fourier transform algorithm can be done in $q \log(q)$ operations.

The corresponding quantum Fourier transform $U_{QFT}$ with base $2^n$ is defined by

$$U_{QFT} : |x\rangle \mapsto \frac{1}{\sqrt{2^n}} \sum_{c=0}^{2^n-1} e^{\frac{2\pi icx}{2^n}} |c\rangle.$$ 

We will see that this can be accomplished in approximately $n^2$ operations rather than $n2^n$. This is an exponential speed-up of the process.
Outline of Shor’s algorithm for factoring

We begin with 2 \( n \)-qubit registers. Apply the Walsh transformation on the first to give a uniform superposition of states:

\[
|0\rangle \otimes |0\rangle \Rightarrow \frac{1}{\sqrt{Q}} \sum_{l=0}^{Q-1} |l\rangle \otimes |0\rangle
\]

Apply a transformation which computes \( y^l \mod N \):

\[
\frac{1}{\sqrt{Q}} \sum_{l=0}^{Q-1} |l\rangle \otimes |y^l \mod N\rangle
\]

Measure the second register:

\[
\frac{1}{\sqrt{A}} \sum_{l=0}^{Q-1} |l\rangle \otimes |y^l_0\rangle = \frac{1}{\sqrt{A}} \sum_{j=0}^{A-1} |j \cdot r + l_0\rangle \otimes |y^l_0\rangle
\]
Apply the quantum Fourier transform over $Z_Q$ on the first register:

$$\frac{1}{\sqrt{Q}} \sum_{k=0}^{Q-1} \left( \frac{1}{\sqrt{A}} \sum_{j=0}^{A-1} e^{2\pi i (jr+l_0)k/Q} \right) |k\rangle \otimes |y^{l_0}\rangle$$

Measure the first register. Let $k_1$ be the outcome. Approximate the fraction $\frac{k_1}{Q}$ by a fraction with denominator smaller than $N$. If the denominator $d$ doesn’t satisfy $y^d = 1 \mod N$, throw it away, else call the denominator $r_1$.

Repeat all previous steps $\text{poly}(\log(N))$ times to get $r_1, r_2, \ldots$

Output the minimal $r$. 
Possibilities for physical implementation

- Implementations of quantum computers will be a difficult experimental challenge. Quantum computer equipment must satisfy a variety of constraints: (1) the qubits must interact very weakly with their environment to minimize decoherence and preserve their superpositions, (2) the qubits must interact very strongly with one another for the logic gates and information transfer to be effective, and (3) the initialization and readout of states must be efficient. Not many known physical systems can satisfy these requirements, although there are some possibilities.
A collection of charged ions held in an electromagnetic trap is one possibility. Each atom stores a qubit of information in a pair of internal electron levels. Each atom’s levels are protected from environmental influences. Scaling to larger numbers of qubits should be able to be done by adding more atoms to the collection. When appropriate laser radiation is applied to the atoms, only one of the two internal states fluoresces. This allows detection of the state of each qubit. The atoms are coupled by virtue of their mutual Coulomb repulsion. Experimental development of trapped ion quantum computation is at the level of single-ion and two-ion qubit systems. Extensions to larger numbers of trapped ions has been difficult, but there do not seem to be impossible theoretical limits to scaling.
• Another system which could be developed into a quantum computer is a single molecule, in which nuclear spins of individual atoms represent qubits. This is the basis of the NMR technique mentioned above. The spins can be manipulated, initialized, and measured. For example, the carbon and hydrogen nuclei in a chloroform molecule can be used to represent two qubits. Applying a radio-frequency pulse to the hydrogen nucleus addresses that qubit and causes it to rotate from a $|0\rangle$ state to a superposition $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ state. Interactions through chemical bonds allow multiple-qubit logic to be performed. However, it is difficult to find molecules with more than 10 spins in them and with a large coupling constant between every pair of spins . . .
Decoherence and error correction

• Decoherence in general arises from interactions with the environment, which typically has the effect of measuring the system and thus collapsing a quantum computation. In addition, we have to be careful about leaving temporary qubits floating around. We can expect them to be entangled with the rest of the system, and thus an observation of the “dust” left behind by intermediate computations could effect a measurement of the system, invalidating later stages. Thus, one emphasis in research on quantum computation has been on how to efficiently avoid leaving any garbage floating about.
• As noted above, error detection/correction is difficult in the quantum environment since we cannot reliably clone an arbitrary qubit. Further, any intermediate measurement of the system for error control is likely to invalidate our computation. There are, however, approaches using polarization encoding schemes for error control.
Prospects

- The history of quantum mechanical algorithms is very brief. There are two main approaches that have resulted in descriptions of efficient quantum computational algorithms: the first is estimates of periodicity that resulted in the factorization algorithm, and the second is amplitude amplification that has led to Grover’s quantum search and related algorithms.

- Over the past 70 or 80 years, physicists have observed various quantum mechanical phenomena that lead to puzzling and even apparently paradoxical results. Most of these still remain to be investigated from a quantum computing perspective.
One interesting question is how slight difference in the laws of quantum mechanics might affect these issues. Some interesting work by Abrams et al. shows that if there was even the slightest amount of nonlinearity in quantum mechanics, it would be possible to modify the amplitude amplification scheme of Grover’s quantum search algorithm to obtain an efficient algorithm solving the NP-complete satisfiability problem. However, most people believe that such nonlinearity probably does not exist because it would also lead to faster-than-light communication, noncausality, and other violations of fundamental physical principles . . .
Finis

“Nature uses only the longest threads to weave her patterns, so that each small piece of her fabric reveals the organization of the entire tapestry.” - Richard Feynman
